The consequence of this resulted in the first clinical trial of gene therapy in 1989, where two children suffering from severe combined immune deficiency (ADA-SCID) were transplanted with T-cells expressing adenosine deaminase (the defective enzyme in patients with this disorder).

Hematopoietic stem and progenitor expansion was further increased in the presence of mesenchymal stromal cells, most likely due to the synergic effects of the growth factor cocktail containing FGF-1 and cell-cell contacts between the cells .

### **The Biochemistry of Hematopoietic Stem Cell Development**

Hematopoiesis is the process by which self-renewing multipotential stem cells give rise to all of the differentiated blood cells (Fig. 78.1). This process involves the coordinated expression of growth factors, some of which act on primitive progenitors that can give rise to multiple cell lineages and others that support clonal maturation of lineage-committed multipotential hematopoietic stem cells (HSCs).

This chapter examines the biochemistry and physiology of the red blood cells. It describes the development of the mature red blood cell through the process of hematopoiesis and the structure of hemoglobin. It also characterizes the structure of the red cell membrane indicating those critically important in red cell function.

Clonal hematopoiesis (CH) and expansion of blood cells derived from a single hematopoietic stem cell is a defining feature of hematologic cancers, but recently CH was also found to be a frequent consequence of aging.

To understand the biochemistry behind HSC development, the cells that make up the vertebrate embryo blood system need some introduction. Blood cell specification occurs at least three separate times in the mammalian embryo – resulting in three de novo waves of hematopoietic cell production (reviewed in [1]).
